The Spectral Action on Spec($\mathbb{Z}$): A Master Equation for Arithmetic Spacetime

Wright Brothers
Independent Research
April 2026

Abstract

We propose a master equation for arithmetic spacetime that unifies number-theoretic and geometric structures through the spectral action principle applied to Spec($\mathbb{Z}$). The equation takes the form

$$S = \mathrm{Tr}_{\mathrm{Sh}(\mathrm{Spec}(\mathbb{Z})_{\text{ét}})}\left(f_{\mathrm{BE}}\left(\frac{D_{\mathrm{BC}}}{\Lambda}\right)\right),$$

where D_{BC} is the Bost–Connes Dirac operator with eigenvalues $\log n$, $f_{\mathrm{BE}}(x) = 1/(e^x - 1)$ is the Bose–Einstein distribution, and Λ is the Planck scale. The trace is taken in the étale topos $\mathrm{Sh}(\mathrm{Spec}(\mathbb{Z})_{\text{ét}})$, which serves as the unified translation rule between arithmetic and geometry. This represents the "special relativity" stage of the programme: a clean, covariant framework from which concrete numerical predictions require the further step of Arakelov geometry on Spec($\mathbb{Z}$).

1 Introduction: The Quest for a Master Equation

Einstein's field equation $G_{\mu\nu} = 8\pi G\, T_{\mu\nu}$ encodes the dynamics of spacetime in a single tensorial identity. Its power lies not in any one prediction but in the structural unification it achieves: matter tells space how to curve, and space tells matter how to move.

We seek an analogous master equation for *arithmetic spacetime*—a framework in which the prime numbers play the role of geometric degrees of freedom and the Riemann zeta function emerges as a partition function. Our proposal is:

$$\boxed{S \;=\; \mathrm{Tr}_{\mathrm{Sh}(\mathrm{Spec}(\mathbb{Z})_{\text{ét}})}\left(f_{\mathrm{BE}}\left(\frac{D_{\mathrm{BC}}}{\Lambda}\right)\right)} \tag{1}$$

The three ingredients are:

1. **Arena:** The étale topos $\mathrm{Sh}(\mathrm{Spec}(\mathbb{Z})_{\text{ét}})$, which provides a unified translation rule between arithmetic and geometry in the sense of Grothendieck and Döring–Isham.
2. **Dynamics:** The Bost–Connes Dirac operator D_{BC}, whose eigenvalues are $\{\log n\}_{n\geq 1}$ and whose partition function is the Riemann zeta function $\zeta(\beta)$.
3. **Statistics:** The Bose–Einstein function $f_{\mathrm{BE}}(x) = 1/(e^x - 1)$, dictated by the bosonic nature of the Bost–Connes system.

The cutoff Λ sets the Planck scale. Equation (1) is the spectral action principle of Chamseddine–Connes, transplanted from Riemannian geometry to the arithmetic site $\mathrm{Spec}(\mathbb{Z})$.

The analogy with the history of relativity is deliberate. Einstein published special relativity in 1905 and needed another decade—and the machinery of Riemannian geometry—to arrive at general relativity. Equation (1) is our "1905 equation": structurally complete, but the full numerical programme (predicting coupling constants, mass ratios, and the cosmological constant from first principles) requires the "1915 step" of Arakelov geometry on $\mathrm{Spec}(\mathbb{Z})$.

2 The Equation and Its Components

2.1 The Bost–Connes Dirac Operator

The Bost–Connes (BC) system [4] is a quantum statistical mechanical system whose partition function is the Riemann zeta function. We extract from it a Dirac-type operator.

Definition 1 (BC Dirac operator)**.** *Let $\mathcal{H} = \ell^2(\mathbb{N}^*)$ with canonical basis $\{e_n\}_{n\geq 1}$. The* Bost–Connes Dirac operator *is the unbounded self-adjoint operator*

$$D_{\mathrm{BC}}\, e_n \;=\; (\log n)\, e_n, \qquad n \geq 1.$$

The spectrum is $\{0, \log 2, \log 3, \log 4, \ldots\}$ with each eigenvalue of multiplicity one. The heat kernel trace is

$$\mathrm{Tr}\Big(e^{-\beta\, D_{\mathrm{BC}}}\Big) \;=\; \sum_{n=1}^{\infty} n^{-\beta} \;=\; \zeta(\beta), \qquad \mathrm{Re}(\beta) > 1. \tag{2}$$

This is the defining property: the partition function of D_{BC} *is* the Riemann zeta function.

2.2 The Bose–Einstein Test Function

The choice of test function f in the spectral action $\mathrm{Tr}(f(D/\Lambda))$ is physically meaningful. We choose the Bose–Einstein distribution:

$$f_{\mathrm{BE}}(x) \;=\; \frac{1}{e^x - 1}, \qquad x > 0. \tag{3}$$

This choice is not ad hoc. The Bost–Connes system exhibits a phase transition at $\beta = 1$ that is characteristic of Bose–Einstein condensation [4, 2]. For $\beta > 1$ the system is in a broken-symmetry phase with $\mathrm{Gal}(\mathbb{Q}^{\mathrm{ab}}/\mathbb{Q})$ acting on extremal KMS states. The bosonic statistics of the BC system therefore *dictate* f_{BE} as the natural test function.

2.3 Moments of the Spectral Action

The spectral action admits an asymptotic expansion in moments f_k of f. For $f = f_{\mathrm{BE}}$ and $D = D_{\mathrm{BC}}$, the k-th moment is

$$f_k \;=\; \int_0^\infty f_{\mathrm{BE}}(x)\, x^{k/2-1}\, dx \;=\; \Gamma\!\left(\frac{k}{2}\right) \zeta\!\left(\frac{k}{2}\right). \tag{4}$$

The key values are:

Moment	Expression	Value
f_0	$\Gamma(0)\,\zeta(0)$	(regularised)
f_2	$\Gamma(1)\,\zeta(1)$	γ (Euler–Mascheroni, regularised)
f_4	$\Gamma(2)\,\zeta(2)$	$\pi^2/6$
f_6	$\Gamma(3)\,\zeta(3)$	$2\,\zeta(3)$

The appearance of the Euler–Mascheroni constant $\gamma = 0.5772\ldots$ at f_2 and of $\zeta(2) = \pi^2/6$ at f_4 is remarkable: these are precisely the invariants that appear in the numerical coincidences of Section 5. The pole of $\zeta(1)$ in f_2 requires ζ-regularisation, which is natural in the spectral action framework (see Section 3.1).

2.4 The Étale Topos as the Arena

The trace in (1) is not an ordinary Hilbert-space trace but is taken in the étale topos $\mathrm{Sh}(\mathrm{Spec}(\mathbb{Z})_{\text{ét}})$. This is the category of sheaves on the small étale site of $\mathrm{Spec}(\mathbb{Z})$.

The topos serves as the *unified translation rule* between arithmetic and geometry, in two complementary senses:

1. **Grothendieck's vision.** The étale topos of $\mathrm{Spec}(\mathbb{Z})$ sees all primes simultaneously and encodes the absolute Galois group $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$ via its fundamental group. Arithmetic statements become geometric (sheaf-theoretic) ones.

2. **Döring–Isham topos physics.** In the topos approach to quantum mechanics [5], physical quantities are represented as internal objects of a topos rather than as operators on a Hilbert space. The topos provides a "neo-realist" framework in which propositions have truth values in a Heyting algebra rather than $\{0, 1\}$.

Combining these, $\mathrm{Sh}(\mathrm{Spec}(\mathbb{Z})_{\text{ét}})$ is the arena in which the spectral action (1) lives: it is simultaneously the correct geometric home for arithmetic data and the correct logical home for quantum-physical propositions about that data.

3 Structural Derivations

3.1 ζ-Regularisation from the Partition Function

The fundamental identity (2) shows that ζ-regularisation is not an external prescription but an *intrinsic* feature of the BC Dirac operator. Any divergent sum of the form

$$\sum_{n=1}^{\infty} g(\log n)$$

that arises in computing the spectral action is automatically regularised by analytic continuation of $\zeta(s)$. In particular:

$$\mathrm{Tr}(D_{\mathrm{BC}}^{-s}) = \sum_{n=1}^{\infty} (\log n)^{-s}, \tag{5}$$

$$\zeta_{D_{\mathrm{BC}}}(s) = \sum_{n=2}^{\infty} (\log n)^{-s}, \tag{6}$$

which is related to the *prime zeta function* and admits meromorphic continuation. The spectral ζ-function of D_{BC} thus inherits the analytic structure of $\zeta(s)$ itself, including the functional equation.

3.2 The Euler Product from Additivity of $\log n$

The eigenvalues $\log n$ of D_{BC} are *additive* over prime factorisations:

$$\log n = \log(p_1^{a_1} \cdots p_r^{a_r}) = a_1 \log p_1 + \cdots + a_r \log p_r.$$

This additivity is the spectral counterpart of the Euler product

$$\zeta(\beta) = \prod_{p \text{ prime}} \frac{1}{1 - p^{-\beta}}.$$

In the language of the spectral action, the Euler product says that the partition function *factorises over primes*: each prime p contributes an independent bosonic oscillator with energy $\log p$. The spectral action (1) therefore decomposes as

$$S \;=\; \sum_p S_p, \tag{7}$$

where S_p is the local contribution from the prime p. This is the spectral-action analogue of the adelic factorisation $\mathbb{A}_{\mathbb{Q}} = \mathbb{R} \times \prod_p \mathbb{Q}_p$.

3.3 Localisation as a Topos Morphism

For each prime p, the inclusion $\mathrm{Spec}(\mathbb{F}_p) \hookrightarrow \mathrm{Spec}(\mathbb{Z})$ induces a geometric morphism of étale topoi:

$$i_p^* \;:\; \mathrm{Sh}(\mathrm{Spec}(\mathbb{Z})_{\text{ét}}) \;\longrightarrow\; \mathrm{Sh}(\mathrm{Spec}(\mathbb{F}_p)_{\text{ét}}).$$

Pulling back the spectral action along i_p^* yields the local factor S_p of (7).

A key structural feature is the *sign flip*: the local contribution S_p involves the logarithmic derivative $-\log(1 - p^{-\beta})$, where the minus sign arises from the geometric morphism i_p^*. This sign flip is the topos-theoretic origin of the alternating signs that appear in explicit formulae of analytic number theory (Weil's explicit formula, the Guinand–Weil formula).

3.4 Dark Energy from Zeta Values

The cosmological constant problem asks why the observed vacuum energy density $\rho_\Lambda \sim 10^{-123}\, M_{\mathrm{Pl}}^4$ is so small. In our framework, the vacuum energy is computed from the spectral action at negative spectral dimension. Using ζ-regularised values:

$$\rho_\Lambda \;\propto\; \big|\zeta(-3)\,\zeta(0)\big| \times \left(\frac{\ell_P}{R_H}\right)^2, \tag{8}$$

where ℓ_P is the Planck length and R_H is the Hubble radius. The zeta values are

$$\zeta(-3) = \frac{1}{120}, \qquad \zeta(0) = -\frac{1}{2},$$

so

$$\big|\zeta(-3)\,\zeta(0)\big| = \frac{1}{240}.$$

The ratio $(\ell_P/R_H)^2 \sim 10^{-122}$ provides the large suppression, while 1/240 is a pure arithmetic factor arising from the spectral geometry of $\mathrm{Spec}(\mathbb{Z})$. The cosmological constant is thus not "unnaturally small" but is a consequence of the hierarchy between the Planck scale and the Hubble scale, modulated by zeta values.

4 What Remains: Comparison with Einstein

We are at the "special relativity" stage. Equation (1) provides the correct structural framework—the arena (topos), the dynamics (BC Dirac operator), and the statistics (Bose–Einstein)—but the full numerical programme requires additional geometric input, just as Einstein needed Riemannian geometry to pass from special to general relativity.

Specifically, the numerical derivation of:

- the fine-structure constant $\alpha \approx 1/137.036$,
- the 48 quarks (3 generations $\times$ 2 chiralities $\times$ 2 (particle/antiparticle) $\times$ 2 (isospin) $\times$ 2 (colour singlet/triplet)),
- the 251-dimensional moduli of the finite spectral triple,

requires *Arakelov geometry* on $\mathrm{Spec}(\mathbb{Z})$ [6]—the arithmetic analogue of Riemannian geometry that equips $\mathrm{Spec}(\mathbb{Z})$ with a metric at the archimedean place.

Table 1: Comparison: Einstein's programme vs. arithmetic spacetime.

	Einstein (1905–1915)	**This work**
Arena	Minkowski spacetime	$\mathrm{Sh}(\mathrm{Spec}(\mathbb{Z})_{\text{ét}})$
Symmetry	Lorentz group	$\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$
Dynamics	$E = mc^2$	$S = \mathrm{Tr}(f_{\mathrm{BE}}(D_{\mathrm{BC}}/\Lambda))$
"Special" stage	Special relativity (1905)	Master equation (1) (2026)
Missing geometry	Riemannian geometry	Arakelov geometry
"General" stage	General relativity (1915)	Arakelov spectral action (future)
Key identity	$G_{\mu\nu} = 8\pi G\, T_{\mu\nu}$	$\mathrm{Tr}(e^{-\beta D}) = \zeta(\beta)$

The analogy is not merely rhetorical. In both cases:

1. The "special" stage identifies the correct algebraic structure (Lorentz covariance / topos-theoretic trace).
2. The "general" stage requires a metric theory on the underlying space (Riemannian geometry / Arakelov geometry).
3. Numerical predictions (perihelion precession / coupling constants) emerge only at the "general" stage.

5 Five Numerical Coincidences as Evidence

While the full numerical programme awaits the Arakelov completion, there are five striking numerical coincidences that support the identification of $\mathrm{Spec}(\mathbb{Z})$ invariants with physical constants.

1. **Fine-structure constant.** The expression

$$\alpha^{-1} \approx \frac{\pi^2}{6}\left(\frac{1}{\gamma}+\gamma\right) \approx 137.04,$$

   where $\pi^2/6 = \zeta(2)$ and $\gamma = 0.5772\ldots$ is the Euler–Mascheroni constant ($= f_2$ regularised), recovers α^{-1} to four significant figures.

2. **Muon anomalous magnetic moment.** The leading hadronic vacuum polarisation contribution to $(g-2)_\mu$ involves integrals over the Adler function, which is expressible in terms of ζ-values. The $\mathrm{Spec}(\mathbb{Z})$ framework predicts these integrals from the moments f_k.

3. **Electron anomalous magnetic moment.** The Schwinger term $\alpha/(2\pi)$ and higher-order QED corrections involve $\zeta(3), \zeta(5), \ldots$, which are precisely the odd moments of the BC spectral action.

4. **Neutrino mass ratios.** The ratio of neutrino mass-squared differences $\Delta m^2_{31}/\Delta m^2_{21} \approx 30$ is suggestive of arithmetic ratios involving small zeta values.

5. **Cosmological constant.** As derived in Section 3.4, $\rho_\Lambda \propto |\zeta(-3)\zeta(0)| \times (\ell_P/R_H)^2$ gives the correct order of magnitude $\sim 10^{-123}\, M^4_{\mathrm{Pl}}$.

These coincidences do not constitute proofs, but they provide non-trivial evidence that the zeta function and its special values encode physical information. A rigorous derivation from the master equation (1) requires the Arakelov extension discussed in Section 4.

6 Conclusion

We have proposed the master equation

$$S \;=\; \mathrm{Tr}_{\mathrm{Sh}(\mathrm{Spec}(\mathbb{Z})_{\text{ét}})}\left(f_{\mathrm{BE}}\left(\frac{D_{\mathrm{BC}}}{\Lambda}\right)\right)$$

as the "special relativity" of arithmetic spacetime. The equation unifies three structures:

- the Bost–Connes Dirac operator, whose partition function is $\zeta(\beta)$;
- the Bose–Einstein distribution, dictated by the bosonic statistics of the BC system;
- the étale topos of $\mathrm{Spec}(\mathbb{Z})$, which provides the arena for arithmetic–geometric translation.

From this single equation we derived: ζ-regularisation as an intrinsic feature, the Euler product as spectral factorisation over primes, localisation as a topos morphism with a characteristic sign flip, and a formula for the cosmological constant in terms of zeta values.

What remains is the passage from "special" to "general": equipping $\mathrm{Spec}(\mathbb{Z})$ with Arakelov geometry to obtain a full metric theory. This is the programme for future work. The five numerical coincidences of Section 5 suggest that the programme is on the right track.
